Prediction of Breeding Values

Peter von Rohr

2023-04-26

Recap Statistical Modelling

- Capture uncertainty due to stochastic relationship
- Components:
  - response variable y
  - predictor variables $x_1, x_2, \ldots, x_k$
  - error term e
  - function $m(x)$

Model Selection

- For fixed effects, select relevant predictors via model selection
- Recommended approach: **backwards-elimination**
  1. start with full model
  2. discard predictor variable that increases residual sums of squares the least and get current reduced model
  3. repeat step 2 until all predictors are eliminated
  4. from above resulting sequence of models, select the one with minimal criterion
- Criterion can be Mallow C_p, AIC or BIC

Variation

- Any new trait can only be used for selection, if variation is found in population
- Since change in trait via selection happens between generations, variation must also be at genetic level
- Use mixed linear effects model to estimate genetic variance, often reported as **heritability**

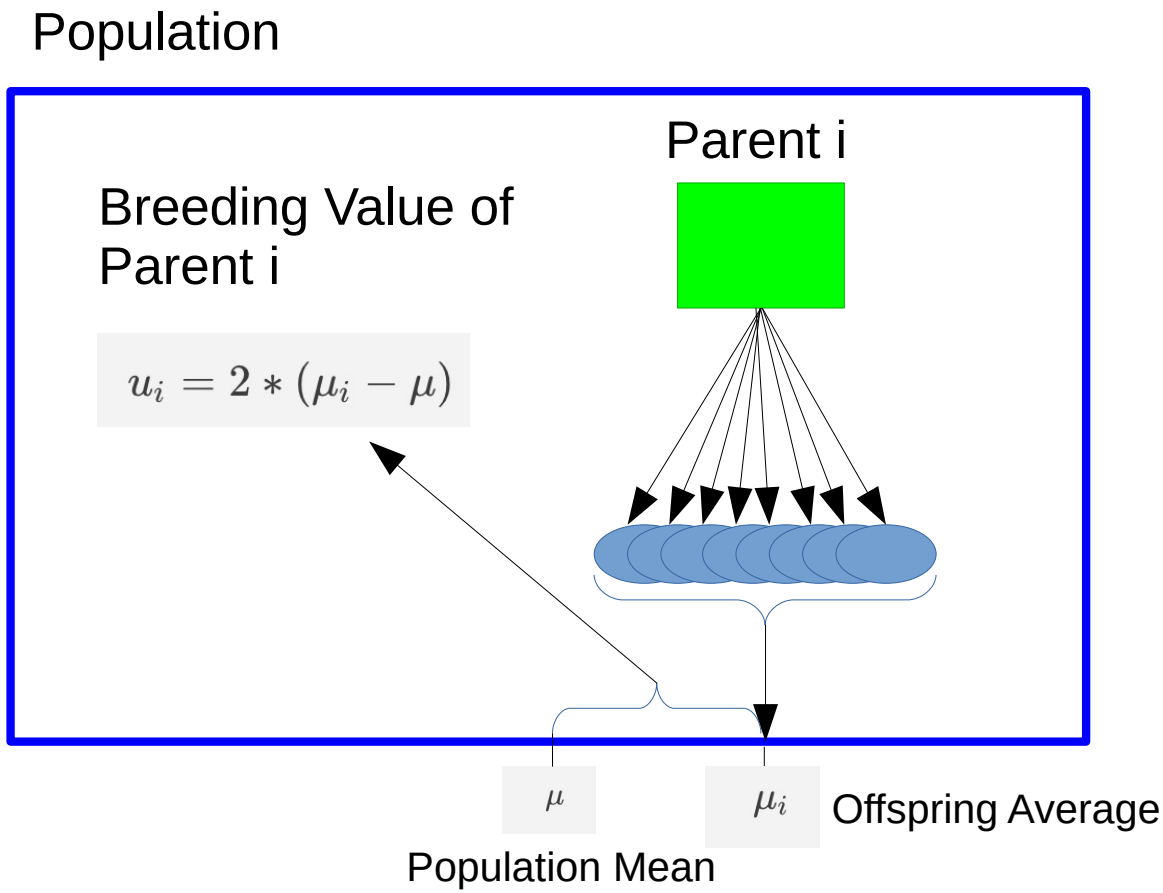
$$h^2 = \frac{\sigma_u^2}{\sigma_p^2}$$

Selection Criterion

- If heritability is confirmed
- Selection criterion is needed
- Animals have to be ranked according to the criterion
- Best animals selected as parents of future generation

What are breeding values

Definition: two times difference between offspring of a given parent from population mean



Practical Considerations

- Definition of breeding value is based on biological fact that parent passes half of its alleles to offspring
- In practice, definition cannot be used
  - breeding values depend on population (allele frequencies)
  - most parents do not have enough offspring
  - breeding values are needed before animals have offspring
  - different environmental factors not considered

Solution

- Use genetic model to predict breeding values based on phenotypic observations
- Genetic model decomposes phenotypic observation (y_i) in different components

$$y_i = \mu + u_i + d_i + i_i + e_i$$

where μ is the general mean, u_i the breeding value, d_i the dominance deviation, i_i the epistasis effect and e_i the random error term.

Solution II

- For predicting breeding values d_i and i_i are often ignored, leading to a simplified version of the genetic model

$$y_i = \mu + u_i + e_i$$

- Expected values and variance-covariance matrix

$$E \begin{bmatrix} y_i \\ u_i \\ e_i \end{bmatrix} = \begin{bmatrix} \mu \\ 0 \\ 0 \end{bmatrix}$$

$$var \begin{bmatrix} y_i \\ u_i \\ e_i \end{bmatrix} = \begin{bmatrix} \sigma_y^2 & \sigma_u^2 & \sigma_e^2 \\ \sigma_u^2 & \sigma_u^2 & 0 \\ \sigma_e^2 & 0 & \sigma_e^2 \end{bmatrix}$$

How to Predict Breeding Values

- Predicted breeding values ($\hat{u}$) are a function of the observed phenotypic data (y)

$\rightarrow \hat{u} = f(y)$

- What should $f()$ look like?
- Goal: Maximize improvement of offspring generation over parents

$\rightarrow \hat{u}$ should be conditional expected value of true breeding value u given y:

$$\hat{u} = E(u|y)$$

Derivation

- Assume: multivariate normality of u and y and $E(u) = 0$, then

$$\begin{aligned}\hat{u} &= E(u|y) = E(u) + cov(u, y^T) * var(y)^{-1} * (y - E(y)) \\ &= E(u|y) = cov(u, y^T) * var(y)^{-1} * (y - E(y))\end{aligned}$$

- $\hat{u}$ consists of two parts

1. $(y - E(y))$: phenotypic observations corrected for environmental effects
2. $cov(u, y^T) * var(y)^{-1}$: weighting factor of corrected observation

Unbiasedness

- Expected value ($E(\hat{u})$)

$$
\begin{aligned}
E(\hat{u}) &= E(cov(u, y^T) * var(y)^{-1} * (y - E(y))) \\
&= cov(u, y^T) * var(y)^{-1} * E(y - E(y)) \\
&= cov(u, y^T) * var(y)^{-1} * (E(y) - E(y)) = 0
\end{aligned}
$$

- With $E(u) = 0$, it follows $E(\hat{u}) = E(u) = 0$

Variance

- $var(\hat{u})$ and $cov(u, \hat{u})$ important for quality of prediction

$$
\begin{aligned}
var(\hat{u}) &= var(cov(u, y^T) * var(y)^{-1} * (y - E(y))) \\
&= cov(u, y^T) * var(y)^{-1} * var(y - E(y)) \\
&\quad * var(y)^{-1} * cov(y, u^T) \\
&= cov(u, y^T) * var(y)^{-1} * cov(y, u^T) \\
cov(u, \hat{u}) &= cov(u, (cov(u, y^T) * var(y)^{-1} * (y - E(y)))^T) \\
&= cov(u, (y - E(y))^T) * var(y)^{-1} * cov(y, u^T) \\
&= cov(u, y^T) * var(y)^{-1} * cov(y, u^T) = var(\hat{u})
\end{aligned}
$$

Accuracy

- Measured by $r_{u,\hat{u}}$
- Recall $cov(u, \hat{u}) = var(\hat{u})$

$$r_{u,\hat{u}} = \frac{cov(u, \hat{u})}{\sqrt{var(u) * var(\hat{u})}}$$
$$= \sqrt{\frac{var(\hat{u})}{var(u)}}$$

- Reliability ("Bestimmtheitsmass"): $B = r^2_{u,\hat{u}}$

Prediction Error Variance (PEV)

- Variability of prediction error: $u - \hat{u}$

$$
\begin{aligned}
var(u - \hat{u}) &= var(u) - 2cov(u, \hat{u}) + var(\hat{u}) = var(u) - var(\hat{u}) \\
&= var(u) * \left[1 - \frac{var(\hat{u})}{var(u)}\right] \\
&= var(u) * \left[1 - r^2_{u,\hat{u}}\right]
\end{aligned}
$$

- Obtained from coefficient matrix of mixed model equations
- Used to compute reliability

Conditional Density

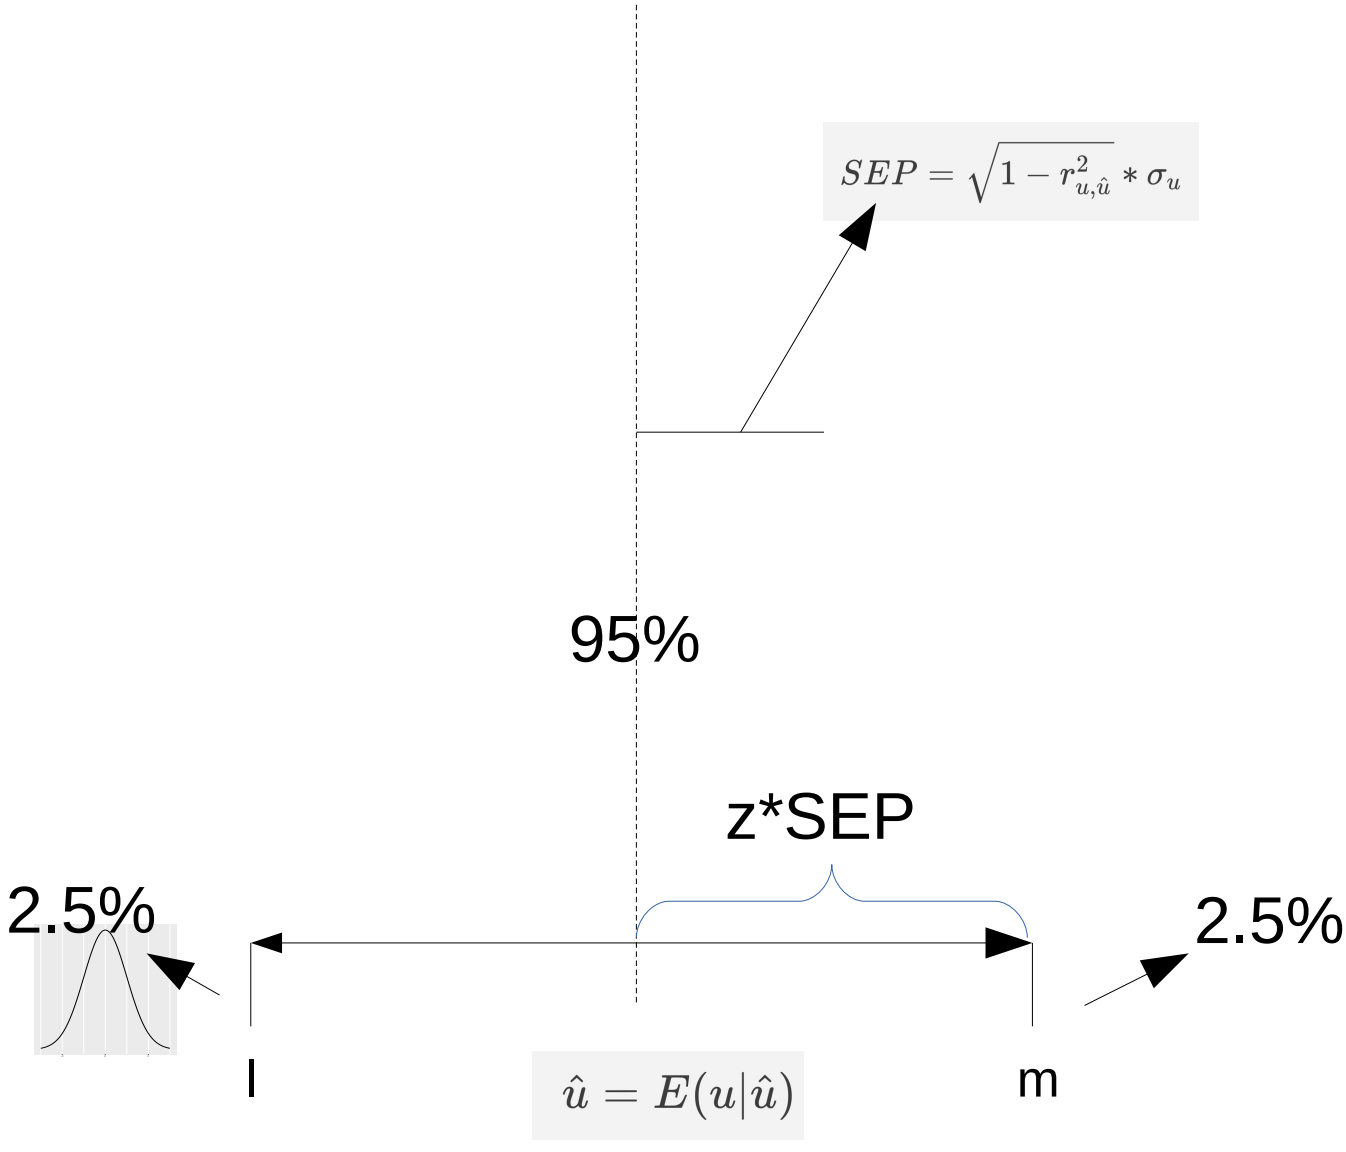
- Assessment of risk when using animals with predicted breeding values with different reliabilities quantified by $f(u|\hat{u})$
- Multivariate normal density with mean $E(u|\hat{u})$ and variance $var(u|\hat{u})$

$$
\begin{aligned}
E(u|\hat{u}) &= E(u) + cov(u, \hat{u}^T) * var(\hat{u})^{-1} * (\hat{u} - E(\hat{u})) = \hat{u} \\
var(u|\hat{u}) &= var(u) - cov(u, \hat{u}^T) * var(\hat{u})^{-1} * cov(\hat{u}, u^T) \\
&= var(u) * \left[1 - \frac{cov(u, \hat{u}^T)^2}{var(u) * var(\hat{u})}\right] \\
&= var(u) * \left[1 - r^2_{u,\hat{u}}\right]
\end{aligned}
$$

Confidence Intervals (CI)

- Assume an error level α, this results in $100 * (1 - \alpha)$%-CI
- Typical values of α 0.05 or 0.01
- With $\alpha = 0.05$, the 95%-CI gives interval around mean which covers a surface of 0.95

CI-Plot



CI Limits

- lower limit l and upper limit m are given by

$$\begin{aligned} l &= \hat{u} - z * SEP \\ m &= \hat{u} + z * SEP \end{aligned} \tag{1}$$

- z corresponds to quantile value to cover a surface of $(1 - \alpha)$
- Use R-function `qnorm()` to get value of z

Linear Mixed Effects Model

- Use more realistic model for prediction of breeding values

$$y = Xb + Zu + e$$

where

y	vector of length n with observations
b	vector of length p with fixed effects
u	vector of length q with random breeding values
e	vector of length n with random error terms
X	$n \times p$ incidence matrix
Z	$n \times q$ incidence matrix

Expected Values and Variances

$$E\begin{bmatrix} y \\ u \\ e \end{bmatrix} = \begin{bmatrix} Xb \\ 0 \\ 0 \end{bmatrix}$$

$$var\begin{bmatrix} y \\ u \\ e \end{bmatrix} = \begin{bmatrix} ZGZ^T + R & ZG & 0 \\ GZ^T & G & 0 \\ 0 & 0 & R \end{bmatrix}$$

Solutions

- Same as for simple model

$$\hat{u} = E(u|y) = GZ^T V^{-1}(y - X\hat{b})$$

with

$$\hat{b} = (X^T V^{-1} X)^- X^T V^{-1} y$$

corresponding to the general least squares solution of b

Problem

- Solution for $\hat{u}$ contains V^{-1} which is large and difficult to compute
- Use mixed model equations

$$\begin{bmatrix} X^T R^{-1} X & X^T R^{-1} Z \\ Z^T R^{-1} X & Z^T R^{-1} Z + G^{-1} \end{bmatrix} \begin{bmatrix} \hat{b} \\ \hat{u} \end{bmatrix} = \begin{bmatrix} X^T R^{-1} y \\ Z^T R^{-1} y \end{bmatrix}$$

Sire Model

$$y = Xb + Zs + e$$

where s is a vector of length q_s with all sire effects.

$$var(s) = A_s * \sigma_s^2$$

where A_s: numerator relationship considering only sires

Animal Model

$$y = Xb + Za + e$$

where a is a vector of length q_a containing the breeding values

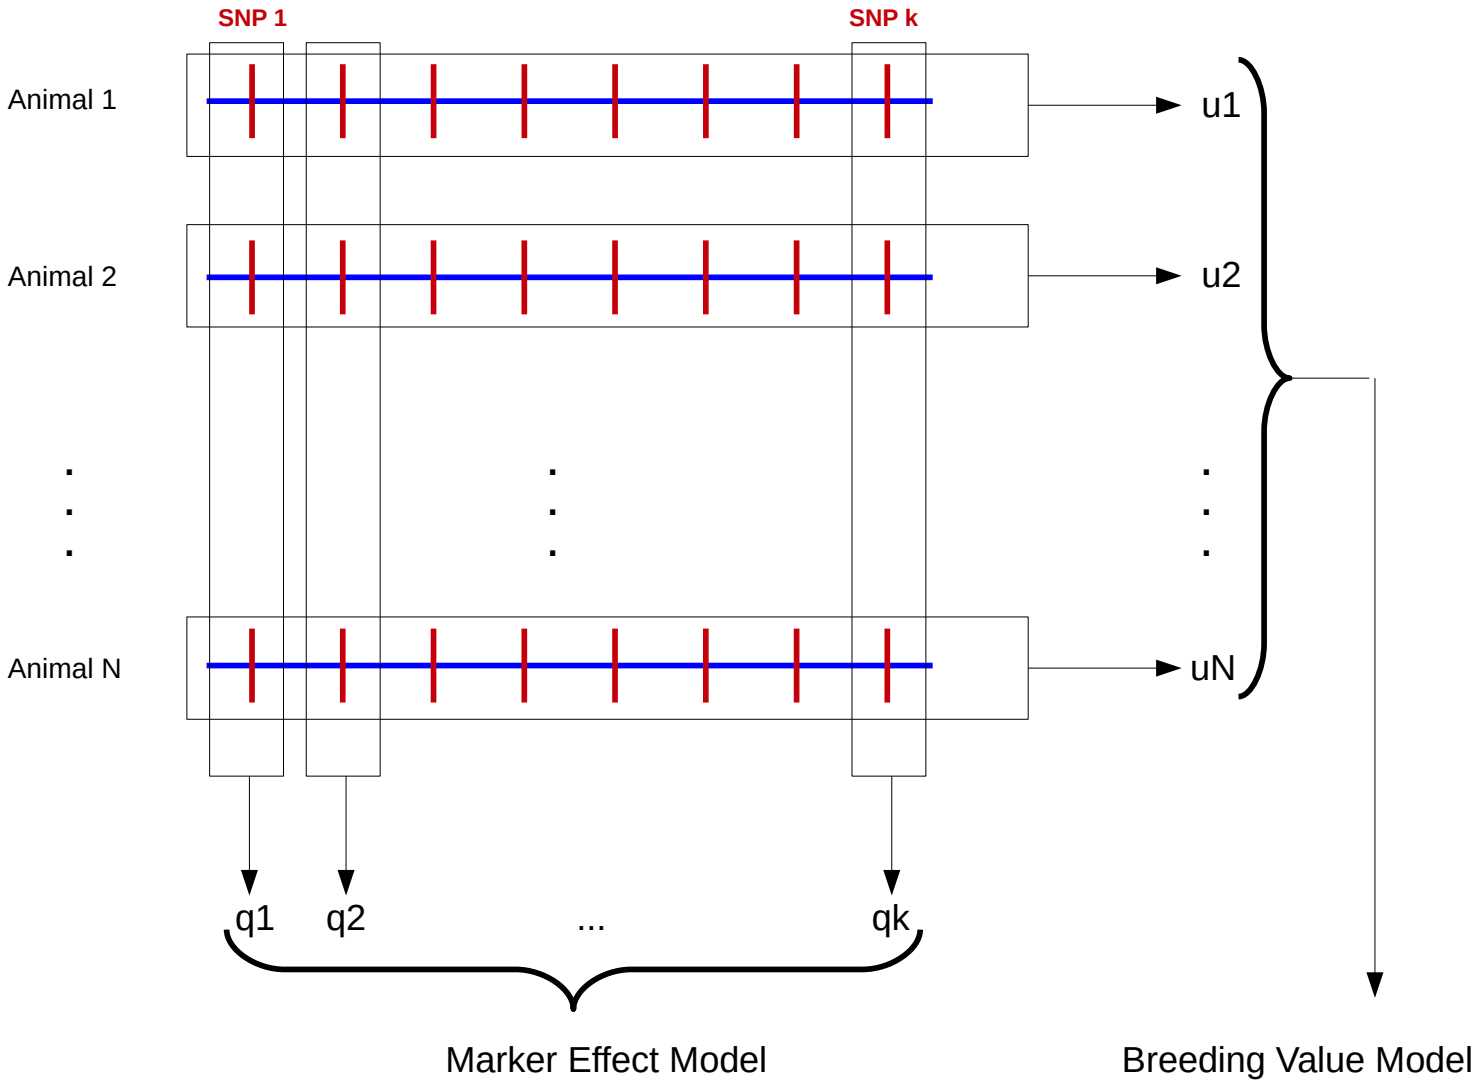
$$var(a) = A\sigma_a^2$$

where A is the numerator relationship matrix

Genomic BLUP (GBLUP)

1. marker-effect models: SNP-loci as random effects (MEM)
2. breeding value based models: genomic breeding values as random effects (BVM)

MEM and BVM



SNP 1
SNP k
Animal 1
Animal 2
Animal N
u1
u2
uN
q1
q2
...
qk
Marker Effect Model
Breeding Value Model

Marker Effect Model (MEM)

- Marker effects (a) as random in a linear mixed effects model

$$y = X\beta + Ma + e$$

- Solution of marker effects via mixed model equations

$$\begin{bmatrix} X^T R^{-1} X & X^T R^{-1} M \\ M^T R^{-1} X & M^T R^{-1} M + I * \sigma_a^{-2} \end{bmatrix} \begin{bmatrix} \hat{\beta} \\ \hat{a} \end{bmatrix} = \begin{bmatrix} X^T R^{-1} y \\ M^T R^{-1} y \end{bmatrix}$$

where σ_a^2 is the SNP-effect variance component.

- Genomic breeding value for animal i is computed as sum over appropriate values of $\hat{a}$ given by genotype of animal i

Breeding Value Based Model

- Genomic breeding values (u) as random effects in linear mixed effects model

$$y = X\beta + Wu + e$$

- Solutions

$$\begin{bmatrix} X^T R^{-1} X & X^T R^{-1} W \\ W^T R^{-1} X & W^T R^{-1} W + G^{-1} * \sigma_u^{-2} \end{bmatrix} \begin{bmatrix} \hat{\beta} \\ \hat{u} \end{bmatrix} = \begin{bmatrix} X^T R^{-1} y \\ W^T R^{-1} y \end{bmatrix}$$

- Genomic breeding values correspond to solutions for $\hat{u}$

How Does GBLUP Work

$$\begin{bmatrix} X^T X & X^T Z & 0 \\ Z^T X & Z^T Z + G^{(11)} & G^{(12)} \\ 0 & G^{(21)} & G^{(22)} \end{bmatrix} \begin{bmatrix} \hat{b} \\ \hat{g}_1 \\ \hat{g}_2 \end{bmatrix} = \begin{bmatrix} X^T y \\ Z^T y \\ 0 \end{bmatrix}$$

- $G^{(11)}$: animals with phenotypic observations
- $G^{(22)}$: animals without phenotypic observations

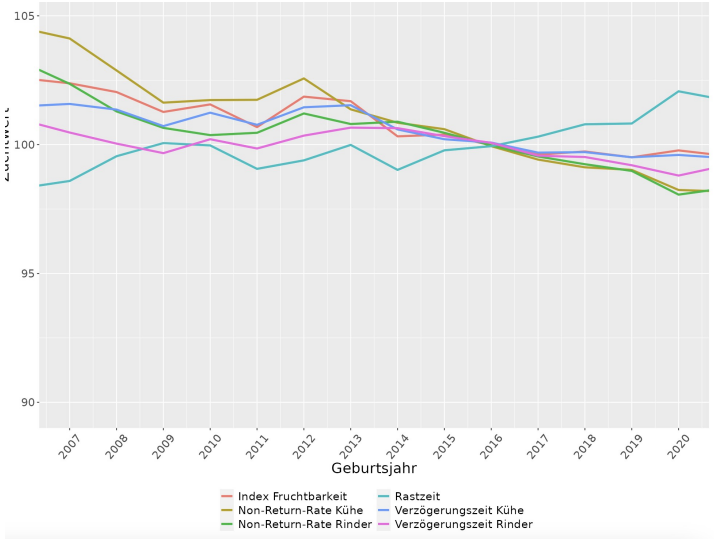
$$\hat{g}_2 = -\left(G^{22}\right)^{-1} G^{21} \hat{g}_1$$

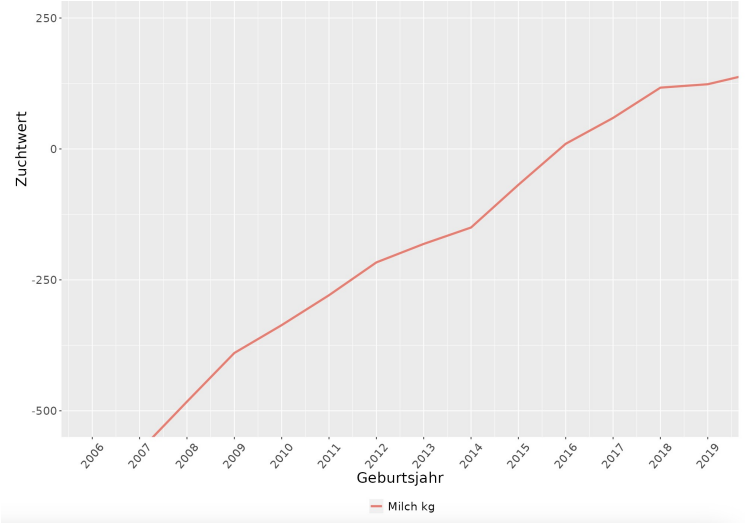
Summary for One Trait

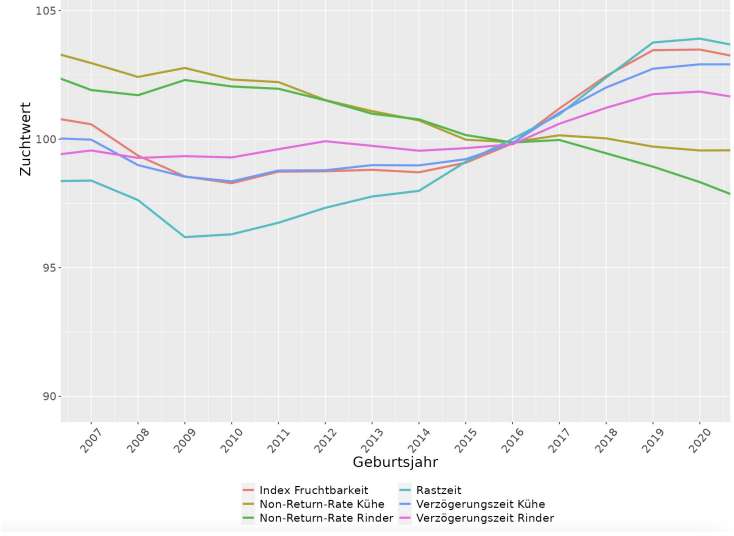
- Predicted breeding values with or without genomic information
- Animals can be ranked according to predicted breeding values
- Problems:
  - Not only one trait should be improved
  - Selection for one trait changes also other traits via correlated selection response

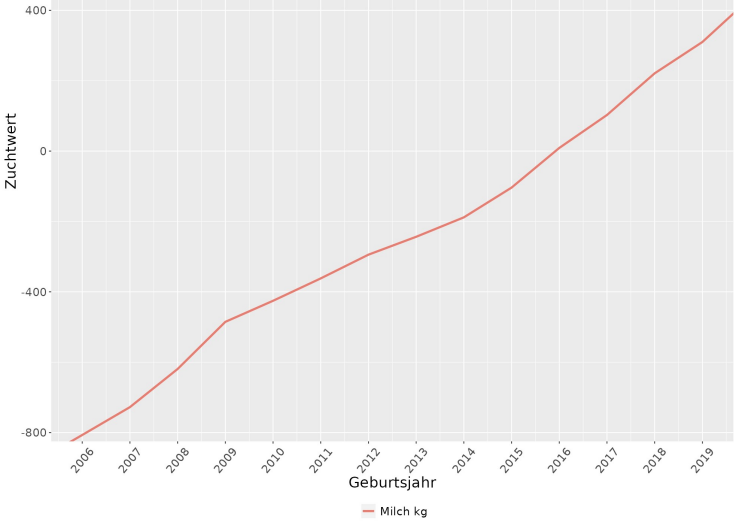
$\rightarrow$ see genetic trends at: https://1-htz.quagzws.com/shiny/users/zws/genTrendHolstein_DE/index.Rmd

Example Fertility and Production

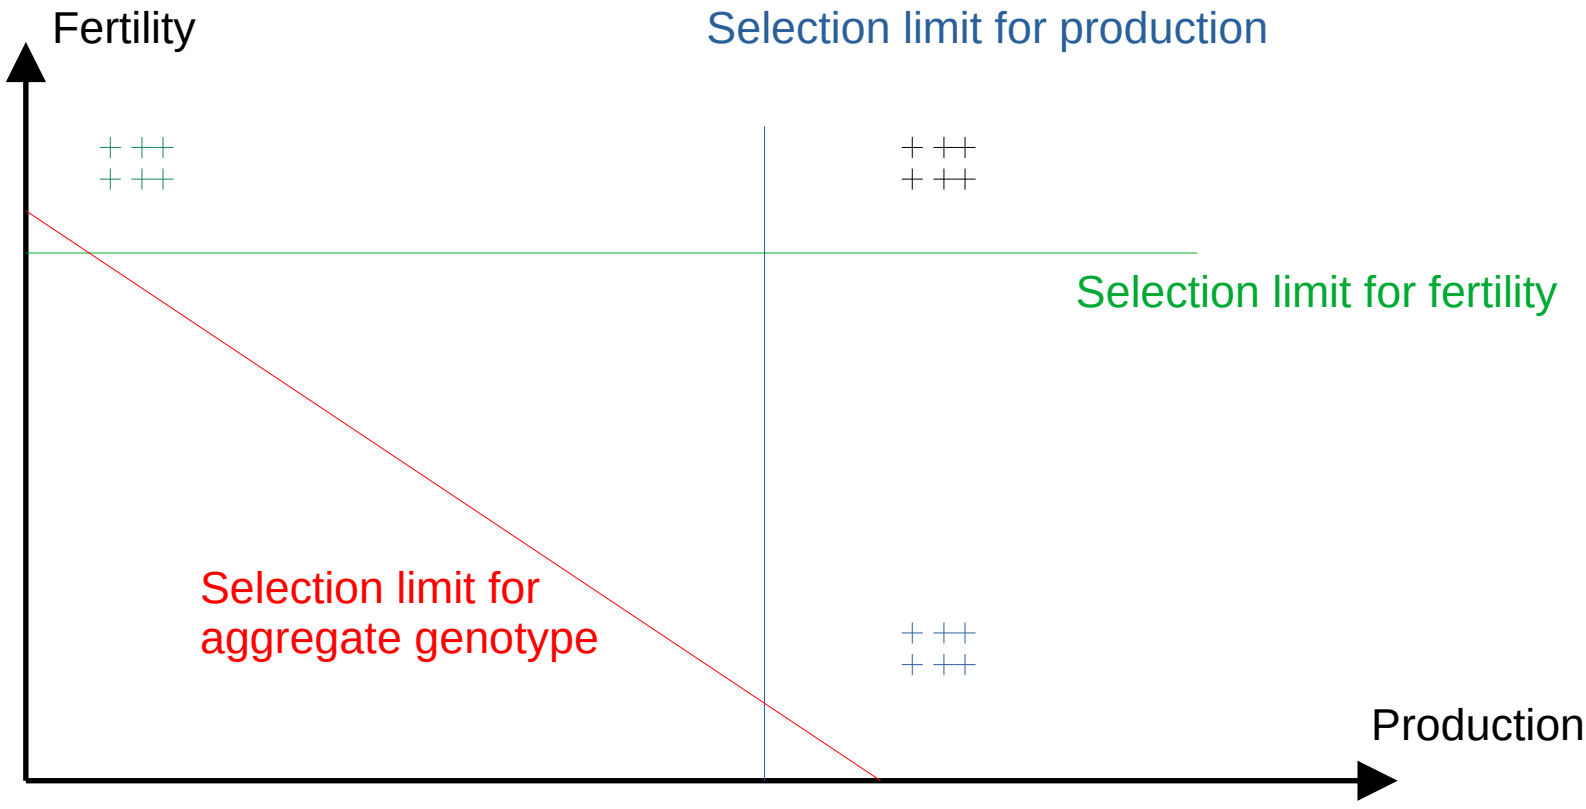








Multi-Trait Selection



Types of Multi-Trait Selection

- Tandem selection
  - select for one trait at the time
  - after goal has been reached change to different trait
- Independent selection limits
  - select only animals which fullfill criteria in all traits
- Selection according to aggregate genotype
  - combine traits into aggregate genotype H
  - define H as weighted sum of true breeding values and economic values
  - use selection index I to estimate H

Aggregate Genotype

Definition in vector notation: $H = v^T \cdot u$

where

- u: vector of true breeding values
- v vector of economic values which are marginal changes in profit for a small change in the population mean of the trait

Estimate H via index I, hence $\hat{H} = I = b^T x$

with

- x: a vector of information sources
- b: a vector of unknown weights.

Determine b such that $var(I - H)$ is minimal.

Find b ...

... such that $var(I - H)$

$$
\begin{aligned}
var(I - H) &= var(I) - 2 * cov(I, H) + var(H) \\
&= var(b^T x) - 2 * cov(b^T x, v^T u) + var(v^T u) \\
&= b^T var(x) b - 2 * b^T cov(x, u^T) v + v^T var(u) v \\
&= b^T P b - 2 * b^T C v + v^T G v
\end{aligned}
$$

Setting $\frac{\partial \ var(I-H)}{\partial b} = 0$ leads to

$$Pb = Cv$$

Hence

$$b = P^{-1} C v$$

Special Case

- Same traits in H and in I
- Use predicted breeding values $\hat{u}$ from multivariate BLUP animal model as information source x
- Then it follows

$$b = P^{-1}Cv = var(\hat{u})^{-1} \cdot cov(\hat{u}, u^T) \cdot v = v$$
